ABSTRACT

With the growing prevalence of sensor and wireless networks comes a new demand for location-based access control mechanisms. We introduce the concept of secure location verification, and we show how it can be used for location-based access control. Then, we present the Echo protocol, a simple method for secure location verification. The Echo protocol is extremely lightweight: it does not require time synchronization, cryptography, or very precise clocks. Hence, we believe that it is well suited for use in small, cheap, mobile devices.

1. INTRODUCTION

Computer scientists are used to studying access control mechanisms where one's identity determines what one is authorized to do. However, in the physical world, identity is not the only thing that matters: often, the physical location of the requester also plays an important role in determining access rights. This suggests studying location-based access control.

Location-based access control in the physical world is easy, natural, and familiar. For example, being able to turn on or off the lights in a particular room *requires* having a physical presence in the room. The very design of the light switch is what enforces the security policy. In contrast, achieving the same kind of guarantee with information systems, such as wireless networks, is less straightforward; it is not simply a matter of putting a switch in the right place. To enforce location-based access control policies on information resources, we need a way to perform *location verification*, where a principal's location is securely verified to meet certain criteria: e.g., being inside a particular room or a specific building.

Location verification enables location-based access control. Once a principal's location has been verified using a protocol for location verification, the principal can be granted access to a particular resource according to the desired policy. This approach is naturally combined with physical security; guards or locks might be used to determine who is allowed to enter a building, then location verification employed to allow wireless access to all those inside. In this way, the location verification problem is the key technical challenge that must be surmounted to implement location-based access control.

Location-based access control has several benefits. Most importantly, it is natural for many applications. One simple policy might allow wireless control of only the lights for the room you are in, or might insist that a company server cease operating if it is taken outside the building. In addition, using location for access control obviates the need to establish shared secrets in advance. Visitors to a building need not obtain wireless encryption keys prior to their visit; instead, the keys could be granted automatically to all physical occupants of the building. Likewise, at the ballpark, fans at a baseball game could receive live scorecards on their wireless devices, while stadium owners could restrict this service to only those actually present in the stadium. It would be quite cumbersome to distribute new keys to all fans attending each game, but location-based access control allows bootstrapping off the existing physical security measures controlling entry to the premises.

In this paper, we study the location verification problem. First, we introduce and define the location verification problem in a careful way (Section 2). Then, we propose a new protocol for location verification, called *the Echo protocol* (Section 3), and we prove its security (Section 4). This work provides a foundation for securely using location in wireless information systems.

2. GOALS AND ASSUMPTIONS

2.1 Problem Statement

There are many natural variants of the secure location problem. We focus on solving the *in-region verification* problem: a set of *verifiers* V wish to verify whether a *prover* p is in a region R of interest. R may be a room, a building, a stadium, or other physical area. The region typically has some sort of physical control to restrict people’s entry into it; the purpose, then, is to control access to resources that are not intrinsically constrained by physical security, such as wireless networks. The verifier infrastructure V may, in some cases, be a distributed system consisting of multiple nodes.

The protocol must run correctly in the face of adversaries. Thus, when p does not in fact have a physical presence inside R , the verifier must be careful not to accept p ’s claim to be in R . Furthermore, if p does have a presence in R , the verifier should accept p ’s claim; otherwise the protocol would not be useful in practice. We therefore require the following two properties to ensure that the protocol is useful and secure:

- *Completeness*: If p and V both behave according to the protocol, and p is in R , then V will accept that p is in R .
- *Security*: If V behaves according to the protocol and accepts p ’s claim, then p , or a party colluding with p , has a physical presence in R .

It is important to distinguish between the problem we are addressing, the in-region verification problem, and the *secure location determination problem*. In the latter problem, V attempts to securely discover the physical location of p . In contrast, in the in-region verification problem, p claims to be in a particular region, and V accepts or rejects the claim. The prover’s location claim serves as a hint for the verifier to confirm or disprove. Framing the problem in terms of secure in-region verification, not secure location determination, simplifies the problem and allows different location determination algorithms to be used.

In fact, it is possible to compose an in-region verification protocol with any location determination algorithm, even a potentially insecure one, without compromising the security of the ultimate guarantee that a prover is in the region. The in-region verification algorithm verifies whether the claimed location is in R or not; thus, p can use an insecure localization algorithm to generate a claimed location that will be securely tested for accuracy by V . At worst, p ’s claim will be rejected; in no case will V believe something about p ’s location that has not been securely checked. The prover p thus has the flexibility to choose any appropriate location determination algorithm, even if it has not been proven secure. After running the determination algorithm, p will know which claims it can plausibly make.

2.2 Assumptions

It is worth considering in more detail what our particular protocol is and is not attempting to do. We list below some of our assumptions:

- **Regions, not points.** We are not attempting to verify the exact location of the prover. In other words, the locations claims we verify are not claims of particular *point* locations (plus or minus some error distance),

but rather just presence in a particular region of interest R . This model accords well with our anticipated applications. We assume that, before the verification protocol begins, both the prover and verifier know the definition of the region R .

- **Only “local” regions.** It is not a requirement to verify *all* location claims; and indeed, there are some location claims we do not even attempt to verify. More specifically, we only attempt to verify location claims for regions R that are “near” V . We will explore more precisely what this means in Sections 3 and 4. The restriction makes sense in light of the proposed application domains: if you have a network of devices scattered through a building, you are typically not interested in regions that are outside the building.
- **RF and sound capability.** The verifier and prover must both be able to communicate using both radio frequency (RF) and sound (typically ultrasound frequencies). We will use both transmission media in our protocol.
- **Bounded processing delay.** The prover must be able to bound its processing delay. We will describe the effects that a loose bound will have on the protocol in Section 4.

2.3 Threat Model

In order to verify the security property, we must consider the protocol with respect to a particular threat model. We assume the verifier nodes are all trusted, and they can communicate securely amongst themselves. In contrast, the prover p might behave maliciously, and we will consider an adversarial prover consisting of multiple colluding nodes, arbitrary computing power, and secure RF (speed of light) communication amongst its own nodes as well as sound generation and detection capability on each of its nodes.

Lastly, by definition, the adversary must not actually have any presence in the region R . Otherwise, it would be able to make a legitimate claim and would not need to attack the protocol.

2.4 Design Principles

We designed our protocol according to the following design principles:

- **Make few resource demands on the prover and verifier.** We would like to limit the computation power and hardware resources necessary to participate in the protocol to an absolute minimum. The real goal is to enable location proofs for a large class of devices.
- **No prearranged setup required.** It should not be necessary for the prover to have previously engaged in a setup or registration step with the verifier. This excludes many cryptographic solutions; even public-key cryptography requires pre-arranged trust relationships, and thus is not suitable for our purposes. By eliminating the setup step, we are enabling access to resources to be granted based on physical presence alone.

In settings where keys have been previously set up, we can use them to complement our protocol. We will discuss a variant of the Echo protocol in Section 4.1

where a challenge-response protocol can be used to verify that a particular principal is inside a given region.

- **Quantitative guarantees.** We would like to provide precise bounds on the uncertainty in the protocol.

2.5 Design Setting

We initiated this work primarily in the context of nodes such as those found in sensor networks. This choice imposes certain design constraints. Briefly, sensor networks are composed of many small, cheap nodes equipped with a variety of environmental sensors. Examples include accelerometers, microphones, and thermometers. The nodes contain a general purpose CPU, though it is often useful only for minimal computation. Finally, the nodes communicate using a wireless network over distances of tens to hundreds of meters. Thus, the sensing capabilities of sensor networks can be used to help bridge the physical-computational gap.

One consequence of considering this domain is that many techniques, such as public-key cryptography, are infeasible. The Berkeley Mica sensor nodes, for example, have 4MHz 8-bit processors with 4KB of RAM [11]. What we need, then, is a lightweight way to perform location verification given many sensor-class nodes. The principal trying to prove its location need not be a sensor-class node, though we do not assume that it is more powerful. The fact that our protocol can work within these tight constraints makes our results all the more meaningful, and we expect that the Echo protocol will be broadly applicable to sensor networks, networked embedded systems, ubiquitous computing, wireless networks, and many other similar application settings.

2.6 Our Contributions

We introduce the secure in-region verification problem. We argue that, for security purposes, the in-region verification problem is a better model to focus on than trying to solve the secure location determination problem directly. This is a novel view of localization.

Second, we present a provably secure protocol for performing in-region verification with minimal hardware requirements.

While our protocols use ultrasound and time-of-flight techniques, neither of these ideas are new: others have previously proposed localization algorithms based on time-of-flight and on ultrasound ranging. Rather, the novel contribution of this paper is to provide a solution to the security problem in localization.

3. OUR DESIGN: THE ECHO PROTOCOL

Next, we describe the design of our proposal for location verification, which we dub the Echo protocol. For expository purposes, we start by considering a simplified toy scenario (Section 3.1); then, we extend it repeatedly (Section 3.2) until we obtain the full protocol (Section 3.3).

Notation. We define s to be the speed of sound, or 331 m/s. Likewise, we will take c to be the speed of light, or 3×10^8 m/s. Define $d(x, y)$ to be the distance between x and y . We define R to be the area in which we would like to verify the location of a prover p . The set of all verifier nodes is denoted by V . N denotes a nonce, i.e., an unpredictable random value.

Figure 1: An illustration of our first simplification of the problem. The prover (not shown here) will try to convince the single verifier node v that it is inside the region R (depicted as a shadowed circle, which in this first scenario is assumed to be centered at v).

1. $p \xrightarrow{\text{radio}} v : \ell$
 2. $v \xrightarrow{\text{radio}} p : N$
 3. $p \xrightarrow{\text{sound}} v : N$

v accepts iff $\ell \in R$ and
elapsed time $\leq d(v, \ell) \cdot (c^{-1} + s^{-1})$.

Figure 2: A protocol that solves our first simplification of the problem.

3.1 Protocol Intuition

Consider first a simplified case, where we have only a single verifier node v , where the region R is a circle¹, and where this circle is centered at v . This scenario is shown pictorially in Figure 1. Now, suppose that the prover claims to be at some location $\ell \in R$ inside the region.

We present a simple protocol for validating the location claim in this restricted case. First note that if the claimed location ℓ is not inside R , then the verifier can reject the claim immediately. Thus, we may safely assume that the prover claims to be inside R . The protocol begins when the verifier node v sends a packet containing a nonce to the prover using RF; the prover immediately echoes the packet back to the verifier using ultrasound. The verifier node v can then calculate how long it should take to hear the echo, namely, the sum of the time it takes to reach ℓ using RF, plus the time it takes for a return packet to go from ℓ to v using ultrasound. Thus, the total elapsed time for the prover to hear the echoed nonce should be about $d(v, \ell)/c + d(v, \ell)/s$ seconds. The only thing v has to do is time this process: If the elapsed time from the initial transmission to reception of the echo packet is more than this amount, the verifier node v rejects the prover's claim; otherwise, if the elapsed time is at most this expected amount, v accepts. This protocol is summarized in Figure 2.

Why does this work? If the prover is able to return the packet in sufficient time, then the verifier is assured that the prover is within $d(v, \ell)$ meters of v . This means that ℓ is known to be inside a circle of radius $d(v, \ell)$ centered at v . Call this circle C ; then we know $\ell \in C$. Since R is defined to be a circle of radius at least $d(v, \ell)$ centered at v , we have

¹In practice, the region is a sphere, instead of circle. However, for simplicity, our discussion will be phrased in terms of circles in the plane. This simplification will make the protocol easier to understand and does not affect the validity of our results.

Figure 3: Diagram illustrating a single verifier at the center of a circular region R where there is an upper bound of Δ on the processing delay. The diagram illustrates the relationship between $\text{ROA}(v, \Delta)$ and $\text{ROA}(v, 0)$, which is equal to R in this case.

$C \subseteq R$, and hence $\ell \in R$. In short, we know that the prover must be inside R .

If the prover cannot return the nonce in sufficient time, it may be for one of two reasons. Either the prover is more than $d(v, \ell)$ meters away from v , or the prover has some processing delay between receiving the RF packet and returning the ultrasound packet. We will explore this latter issue in the following section.

What if the prover tries to cheat by delaying his response? This attack only increases the total elapsed time of the process, thereby making the verifier reject. Intuitively, the longer it takes to complete the protocol, the farther away the prover appears to be. It is not in the prover's interest to appear to be farther from v , because this will put the prover's apparent location outside of R , hence making v reject the prover's claim.

Can the prover cheat by starting the transmission of the response early? No, this attack is not possible. The nonce in the packet prevents the prover from sending a reply before it has received the outgoing RF packet. Hence, the speed of light and sound prevents the prover from pretending to be closer to v than he really is.

3.2 Processing Delay & Nonuniform Regions

In this section, we present a slightly more advanced protocol that addresses three additional issues: the fact that the prover has a non-zero processing delay, the fact that packets take nonzero time to transmit, and the fact that R might not be a circle. We base this protocol on the simple protocol presented in the previous section.

Processing delay. Let us first address the prover's packet processing delay. We will start with the configuration mentioned in Section 3.1: We have a single verifier located at the center of a circular region R . In the ideal case, the prover can receive the RF packet from the verifier node and send out the response over ultrasound instantly; in practice, this is not possible, as the prover will require some time to process the incoming packet. Suppose the prover can bound its processing delay to be at most Δ_p seconds and can make the verifier node aware of this maximum delay. Then, if the prover claims to be at ℓ , the verifier node can compute the time for a prover actually at ℓ to get the packet back: the time for the RF signal to travel from v to ℓ , a processing delay of at most Δ_p , and finally the time for the sound to travel from ℓ back to v .

Now we have a problem: A malicious prover could submit a location claim ℓ at the border of R and grossly overstate its true processing delay to be some very large Δ_m . If, however, the prover's true processing delay were zero, then it could fool the verifier node into thinking that it was inside R when in fact it wasn't. Since the verifier allows up to Δ_m processing delay while the adversary has no delay, the adversary could be $\Delta_m \cdot (c^{-1} + s^{-1})^{-1} \approx \Delta_m \cdot s$ meters outside of R and the verifier would still accept the claimed location, violating our security condition.

The solution to such a problem is for the verifier node to shrink the allowable region in which location claims are accepted. If the prover claims a maximum processing delay of 0, then the protocol presented earlier in Section 3.1 is sufficient. If, however, the prover claims a processing delay of $\Delta_p > 0$, the verifier should not engage in the protocol if the claimed location ℓ is within $\Delta_p \cdot s$ of the outside border. Thus, we define the term *Region of Acceptance* (ROA) to be the area in which the verifier node v is sure that it can correctly verify claims for a prover. Note that this region depends on Δ_p . We write $\text{ROA}(v, \Delta_p)$ to indicate the region where location claims are permitted by v , if the claimed processing delay is Δ_p . See Figure 3 for an illustration.

As stated above, $\text{ROA}(v, \Delta_p)$ is a circle centered at v and fully contained within R . Its radius is $\Delta_p \cdot s$ less than R 's radius (since R was assumed to be a circle). Amending our prior protocol, the verifier should engage in the protocol only if the location claim ℓ is within $\text{ROA}(v, \Delta_p)$. For $\Delta_p = 0$, we have $\text{ROA}(v, 0) = R$, and so the simple protocol presented earlier is a special case of the amended protocol.

We note at this point that if the prover has a processing delay of Δ_p , the protocol is not *complete*. Recall that the completeness condition from Section 2.1 requires that the verifier always accept if the prover is inside R and behaving properly. Yet, for a processing delay of Δ_p , our verifier will not accept location claims that are in the annulus $R \setminus \text{ROA}(v, \Delta_p)$, so our protocol cannot be fully complete.

This suggests an alternate way to view $\text{ROA}(v, \Delta_p)$: it is the region for which the protocol is complete. In other words, $\text{ROA}(v, \Delta_p)$ is the region where a verifier will accept location claims from a correctly functioning prover with processing delay less than Δ_p . We will define the *coverage* of the ROA as the ratio between the area of the ROA and the area of R . A coverage of 100% indicates that the protocol is complete; a coverage of less than 100% indicates only partial completeness.

Packet transmission time. There is another source of uncertainty: the time it takes to actually transmit packets. Each link, radio and ultrasound, has some finite transmission bandwidth. If we are not careful about when we start and stop timing, an attacker could exploit the transmission time to launch an attack. The key is that if the bandwidths in each direction are not the same, the attacker could simply guess the first (or last) few bits of the nonce and send them preemptively.

The attacks in question depend on how timing is performed. We can start timing either before the first bit or after the last bit of the outgoing nonce from the verifier to the prover, and likewise stop timing before the first bit or after the last bit of the incoming nonce. We shall show that in a given situation only some choices are secure; which choices those are depends on the bitrates of the radio and

Figure 4: A single verifier v , inside a irregular region R . We are interested in proving that the prover is within R . The larger circle represents $\text{ROA}(v, 0)$, the area in which v is useful for location verification proofs. This is the largest circle centered at v and wholly contained within R . The inner circle represents $\text{ROA}(v, \Delta)$, the region in which v will accept location claims from a device that is able to bound its processing delay by Δ .

ultrasound links. An important note is that the bitrate, i.e., the bandwidth, of each link is distinct from the propagation speed of waves in the relevant medium, which determines the latency of the link. Even though radio waves travel orders of magnitude faster than ultrasound waves, in practice the bitrates of each may often be comparable. For the sake of the following discussion, let us call the outgoing bandwidth b_o and the incoming bandwidth b_i .

Suppose the verifier stops its timer upon receiving the first bit of the nonce, and suppose $b_o > b_i$. Then the attacker could start sending a few randomly guessed bits of the nonce slightly *before* actually receiving it. The verifier would then infer the prover to be closer than it actually is. Although the attack approach would only work probabilistically, it would only take a few tries to succeed on a few bits. Therefore if $b_o > b_i$, the verifier must stop its timer only after receiving the last bit of the nonce.

Analogously, if the verifier starts timing after the entire nonce has been sent and $b_i > b_o$, then the attacker could guess and then send the last few bits without having received them.

To be safe from such attacks, then, the verifier should start timing before sending the first bit of the nonce, and stop timing after receiving the entire nonce. Unfortunately, this increases the overall uncertainty, so that $\Delta_p \geq \frac{n}{b_o} + \frac{n}{b_i}$ where p is any prover and n is the nonce length. If we know in a particular deployment that one or the other bandwidth is higher we need not be conservative on both ends, since they are mutually exclusive. We assume that the prover takes this contribution to the delay into account when calculating Δ_p ; the constraint will be checked by the verifier, so the prover needs to add this lower bound to any processing time.

Non-circular regions.. Up until now, we have been assuming that R is a circle centered at v . However, that is not always a realistic assumption: perhaps we are interested in verifying location claims in a square room, for instance. We will now relax that assumption and assume that the verifier node is contained somewhere within an arbitrarily shaped

region R . This causes a larger area to be *incomplete*, or non-verifiable, as shown in Figure 4. We will address incompleteness in the next section with our final iteration of the protocol.

Previously, $\text{ROA}(v, 0)$ had been equivalent to R . But this will not work when R is not a circle centered at v . Since we are assuming that our communications equipment is omnidirectional and that signals travel at the same speed in all directions, the ROA must be a circle. Furthermore, the ROA must be wholly contained within R . By definition, the ROA is the region where the verifier will accept a correctly functioning prover; if the ROA were not fully contained within R , the prover could accept a location claim for a prover outside of R , which would be unacceptable. Furthermore, we would like to maximize the area of the ROA since a larger ROA leads to a larger coverage. Thus, $\text{ROA}(v, 0)$ should be the largest circle that fits within R ; in other words, it should be the largest circle that is tangent to R and still contained within it.

We now extend the protocol to handle non-circular regions R where the verifier can bound its processing delay to be at most Δ_p . Recall that both the prover node and verifier node know R *a priori*. Using this, the verifier node can compute ahead of time the region $\text{ROA}(v, 0)$.

The protocol then proceeds as follows: the prover first broadcasts its claimed location ℓ and processing delay Δ_p to the verifier. If $\ell \notin \text{ROA}(v, \Delta_p)$, the verifier should immediately reject the location claim since it will not be able to definitively validate the claim. Otherwise, the verifier node broadcasts a nonce to the prover; the prover echoes the nonce back over ultrasound. The verifier can again time the communication: if it is no greater than the time for the signal to travel out and back and allowing for processing delay, the verifier accepts the location claim.

3.3 Full Protocol Description: The Echo Protocol

In the final iteration of the protocol, we introduce multiple verifier nodes in an attempt to increase the coverage of R . Recall that if R is not a circle, no single node can provide 100% coverage. Consequently, multiple verifiers are needed. Intuitively, we will run the protocol presented in Section 3.2 after selecting one verifier from among the set of verifiers V .

The protocol is quite simple. See Figure 6 for the complete definition. First, a verifier is chosen so that the claimed location ℓ lies within that verifier's ROA. If no such verifier exists, execution is aborted, since the claim can not be verified. After choosing a verifier v to participate, v sends a packet to p using RF, which is echoed back to it using ultrasound. v can calculate how long it should take to hear the echo, namely, the sum of the time it takes to reach ℓ using RF, plus Δ_p , plus the time it takes for a return packet to go from ℓ to v using ultrasound. If the measured elapsed time exceeds this anticipated time, v rejects the location claim. The nonce in the packet prevents the prover from sending a reply before it has received the outgoing RF packet.

The extra verifier nodes serve to expand the region of acceptance within R . Thus, while $\text{ROA}(v, \Delta_p)$ refers to the region that one particular verifier node can accept, we define $\text{ROA}(\Delta_p)$ to be the region where at least one verifier node can prove location claims. It is then clear that

$$\text{ROA}(\Delta_p) \equiv \bigcup_{v \in V} \text{ROA}(v, \Delta_p)$$

Figure 5: The relationship between $ROA(v)$ (for a single verifier v) and the aggregate ROA. Each gray circle represents $ROA(v, \Delta)$ for a particular verifier v . Taken collectively, the gray region represents $ROA(\Delta)$, the aggregate region in which the set of verifiers can successfully verify the location of a prover that features a processing delay less than Δ . Note that $ROA(\Delta)$ is wholly contained within R .

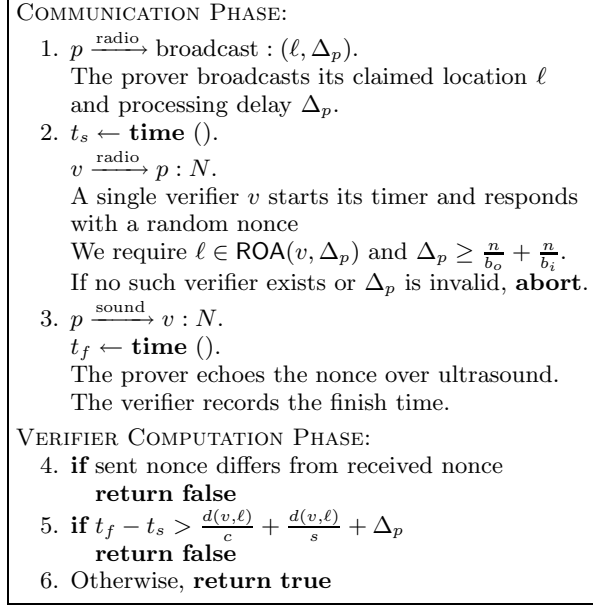

Figure 6: Formal description of the Echo protocol, which can perform location verification in an arbitrary region R with multiple verifier nodes. We represent the prover node as p and the verifier node that runs the protocol as v .

since the set of verifiers can accept a location proof if the claimed location is inside at least one verifier's region of acceptance.

In the Echo protocol, the infrastructure chooses a single verifier node to participate in the protocol. A verifier v may participate if $\ell \in ROA(v, \Delta_p)$, since by definition that is the region that it can perform secure location verification proofs. Note that the claimed location ℓ may be inside $ROA(v, \Delta_p)$ for many different verifier nodes v , hence more than one verifier node might be eligible for participation in the protocol. We only require one to be chosen, and we allow the verifiers to use any convenient leader election mechanism for choosing which particular verifier node will run the protocol. They may have a purely deterministic mechanism for electing verifiers, or they may use a dynamic algorithm in an attempt to conserve power, for example.

4. ANALYSIS

4.1 Security Analysis

As explained in Section 3, the Echo protocol relies on timing: the amount of time it takes to get a response from the prover bounds how far the prover can be from the verifier. We will now show that it is impossible for an adversary outside R to convince the verifier that it is in R .

Proof of security. The heart of the argument is that an attacker would not be able to get the sound signal to the verifier in time. In order to confirm that the prover is at ℓ , all a particular verifier node v must do is verify that the incoming sound signal, which includes the outgoing nonce, is received within

$$t_{\max} \leq \frac{d(v, \ell)}{c} + \frac{d(v, \ell)}{s} + \Delta_p \text{ seconds,}$$

where $d(v, \ell)$ is the distance from the verifier to the claimed location, c is the speed of radio propagation (approximately the speed of light), s is the speed of sound, and Δ_p is the prover's processing delay. As described in Section 3.2, Δ_p includes the packet transmission time. This is checked by the verifier in step two of the communication phase of the protocol. Recall that v agrees to run the protocol only if $\ell \in ROA(v, \Delta_p)$, i.e., if the circle of radius $d(v, \ell) + \Delta_p \cdot s$ lies wholly within R . By definition, the attacker A is outside R ; thus we have

$$d(v, A) > d(v, \ell) + \Delta_p \cdot s.$$

Let t_{finish}^A denote the time at which the attacker finishes sending its response (message 3 of the Echo protocol). The attacker has only two choices: either guess at least some of the bits of N , or learn the entire nonce N from v . In the former case, the attacker's success probability can be made negligibly small by choosing N from a set of sufficient size. In the latter case, it will take at least $d(v, A)/c$ seconds after v first reveals N before A can receive N , because no signal can travel faster than the speed of light. Because v reveals N for the first time in message 2 of the protocol, $t_{\text{finish}}^A \geq d(v, A)/c$ in this case. Now, since the attacker cannot finish transmitting its response before it has received the entire nonce, and because the attacker's response cannot travel faster than the speed of sound, the minimum time required

for the attacker to hear N and get a response to v is

$$\begin{aligned}
t_{\min}^A &= t_{\text{finish}}^A + \frac{d(v, A)}{s} \\
&\geq \frac{d(v, A)}{c} + \frac{d(v, A)}{s} \\
&> \frac{d(v, \ell) + \Delta_p \cdot s}{c} + \frac{d(v, \ell) + \Delta_p \cdot s}{s} \\
&\geq \frac{d(v, \ell)}{c} + \frac{d(v, \ell)}{s} + \frac{\Delta_p \cdot s}{c} + \frac{\Delta_p \cdot s}{s} \\
&\geq \frac{d(v, \ell)}{c} + \frac{d(v, \ell)}{s} + \Delta_p.
\end{aligned}$$

Consequently, the attacker’s signal cannot reach the verifier before the deadline. Note that nowhere in our analysis did we rely on *which* verifier node was used. The only difference would be in the magnitude of the error terms and, therefore, in the chance that the location claim would even be accepted for verification. The attacker does not gain any advantage by selecting a different verifier from the one elected to participate.

Attacks. One possible attack could exploit the difference in propagation speed of sound in different media. If the verifier’s estimation of s is slower than the actual one, then the proof above does not apply. If this is a valid threat model—say there is a lot of metal near the verification region that is capable of transmitting sound from the outside—then the verifier’s estimation of s should be adjusted. This can be done once on a site-specific basis. An alternate defense would be to have other verifier nodes confirm the estimate of s based on when the sound signals are received.

More generally, we require that there be no way for an attacker to generate sound waves from afar without being subject to speed-of-sound delays. For instance, if a remote attacker could call up some person in R over the telephone, convince the victim to put the call on speakerphone, intercept message 2 from afar using a large antenna, and transmit the appropriate ultrasonic signal (i.e., message 3) over the telephone with sufficiently high fidelity, then the attacker might be spoof his location. The key is that the attacker has evaded the speed-of-sound limit on signal propagation by exploiting the ability to remotely actuate a loudspeaker located inside R . We expect such “remote actuation” attacks will be very difficult to mount in practice, for several reasons. Nonetheless, this example illustrates a crucial security assumption: we assume that low-delay remote actuation of sonic signals is infeasible.

Variants We Rejected. One might also consider the implications of other variants of the protocol, where the use of sound and radio for the outgoing and incoming signals is changed from (radio, sound) to (radio, radio), (sound, radio), or (sound, sound). If radio communication is used in both directions, then the error term $\Delta \cdot c$ would be very large (10^5 to 10^6 times as large as the sound case), and it is quite likely that the verifier would not accept location claims at all, since the error might exceed the size of R itself! Thus, at least one of the two directions should use sound.

Why did we reject (sound, radio)? There is a subtle attack. If sound is used in the outgoing direction, an attacker might be able to break security by using laser-based remote “bugging.” The trick is to bounce a laser off a window within

COMMUNICATION PHASE:

1. $p \xrightarrow{\text{radio}}$ broadcast : (ℓ, Δ_p) .
The prover broadcasts its claimed location ℓ and processing delay Δ_p .
2. $t_s \leftarrow \text{time}()$.
 $v \xrightarrow{\text{radio}}$ $p : N$.
A single verifier v starts its timer and responds with a random challenge.
We require $\ell \in \text{ROA}(v, \Delta_p)$ and $\Delta_p \geq \frac{n}{b_o} + \frac{n}{b_i}$.
If no such verifier exists or Δ_p is invalid, **abort**.
3. $p \xrightarrow{\text{sound}}$ $v : F_k(N)$.
 $t_f \leftarrow \text{time}()$.
The prover answers the challenge with a response over ultrasound.
The verifier records the finish time.

VERIFIER COMPUTATION PHASE:

4. **if** $F_k(N)$ differs from received response
 return false
5. **if** $t_f - t_s > \frac{d(v, \ell)}{c} + \frac{d(v, \ell)}{s} + \Delta_p$
 return false
6. Otherwise, **return true**

Figure 7: A variant of the Echo protocol. It authenticates that some principal possessing the key k is in the region R .

R and analyze the return signal to detect the vibration of the window, which would allow a sophisticated attacker outside R to “bug” a room within R from miles away without being subject to speed-of-sound delays on the propagation of the sonic signal. Thus, “remote bugging” attacks effectively speed up the transmission speed of the sound wave and thereby invalidate our security proof above.

The (radio, sound) protocol is more secure against such attacks, because “remote actuation” seems significantly more difficult than “remote bugging,” and the security of the (radio, sound) bugging rests only on the difficulty of “remote actuation” and not on the hardness of “remote bugging.” For this reason, the Echo protocol uses radio in the outgoing direction and reserves ultrasound for the return signal from the prover.

Variant: The Keyed Echo Protocol. Up until now, we have assumed that there are no pre-shared keys that can be used to verify location claims. If, however, there has been a key previously exchanged between the prover and the verifier, the verifier can verify that a *particular* prover is inside a region. This can be used to restrict resources to a principal who is also inside a particular room, for example.

The protocol, formally described in Figure 7, is very similar to the Echo protocol. The prover uses a challenge-response mechanism instead of merely echoing the nonce. More formally, the verifier still sends out a nonce N as before; the prover, however, responds with $F_k(N)$. We require F to be a pseudorandom function, such as AES or SHA1-HMAC. Here k is a key shared between both endpoints and used solely for this purpose. In this way, the verifier is assured that the challenge can only be correctly answered by the principal with the key k . The rest of the protocol remains the same.

4.2 Coverage

The Echo protocol requires that all the verifiers must be inside the region of interest, R . Furthermore, the region of acceptance is a subset of the region of interest and is determined by the placement of the verifiers within R . Thus, a natural question to ask is how well the verifiers “cover” a given region R . We define coverage to be the fraction of the region in which successful location claims can be validated. Obviously, the ideal scenario would allow full coverage with only a few verifiers. In that case, the verifiers would be *complete*, according to our definition in Section 2.1. Recall that the completeness condition requires that the verifiers accept if the prover has a presence inside R . When the coverage is less than 100%, completeness is only partial.

To measure this effect, we ran simulations to measure the coverage in two scenarios with only a few nodes. In Figure 8(a), we placed 10 nodes in a 100m by 100m room. The nodes were randomly placed with the constraint that each node had to be 20m away from every other node; the approach is called “constrained random” since it allows imprecise deployment based on a rough model of the area. In the pictured trial, the placement achieved 81% coverage; averaging 5 trials yielded a mean coverage of 78%.

By manually placing 5 nodes, we were able to achieve a coverage of 93% in a similar room (see Figure 8(b)). Thus, with very few verifier nodes, the ROA covers a significant fraction of the region that we are interested in. The regions with the least amount of coverage are as expected: at the edges and corners of the region.

Although there are a number of possible policies that might be employed to get good coverage, we feel that using a simple model of the site along with the “constrained random” approach will yield good results with little effort. Of course, coverage can always be further increased by adding more verifier nodes.

4.3 Evaluation

The Echo protocol is explicitly designed to make few demands on the prover and verifier.

First, we do not use cryptography. By avoiding the use of both public- and private-key cryptography, we achieve two goals. We lower the CPU and memory requirements on both the prover and verifier, and perhaps more significantly, we remove the need for any prior agreement between the prover and verifier with respect to keys or certificates. This means that if R is, say, a baseball stadium, then any fan attending the game with a suitable small device can act as a prover.

Several authors have proposed schemes that rely on time-of-flight measurements of radio signals. However, such approaches require processing speeds fast enough that distance errors are small even with speed-of-light communication. In contrast, error in our scheme is correlated to the speed of sound, which is roughly 10^6 times slower than radio communications. That means that a correspondingly greater processing delay can be tolerated, which is crucial, if low-cost devices are to participate.

Lastly, our protocol does not require time synchronization between any two nodes. It only requires that each node have a clock that can measure real time with some precision. For example, taking the speed of sound to be 331 m/s, each 1ms of timing inaccuracy in the receiver would increase uncertainty by about 1/3 of a meter. If the prover and verifier are 50m apart, the protocol runtime is about 150ms; clock

skew is unlikely to be more than a few microseconds during this interval [8], so the uncertainty added would be on the order of millimeters, which is acceptable for our application domain.

5. RELATED WORK

A number of authors have proposed using time-of-flight measurements and the speed of light to securely gain location information about untrusted parties. Brands and Chaum proposed a time-bounded challenge-response protocol [4] as a defense against man-in-the-middle attacks on cryptographic identification schemes. Hu, et al., proposed using temporal packet leases for wireless networks to defend against similar attacks [12]. However, a major limitation of these schemes is that both the prover and verifier send RF signals, requiring a much more accurate timing system at the verifier as well as tight real-time processing guarantees on both the prover and verifier for accurate readings. For these reasons, we believe our algorithm is better suited to mobile devices than those previous proposals.

In independent and concurrent work, Waters and Felten present a scheme that uses round-trip time-of-flight of RF signals to achieve goals similar to ours [19]. Their architecture is similar to ours, in that they, too, suggest focusing on secure location verification rather than on secure location determination. However, their reliance on RF seems likely to limit deployment, like the previous proposals mentioned above. Additionally, by using tamper-resistant trusted devices, they are able to defend against stronger adversaries. If their verifier accepts, they can successfully show that the trusted device is at the specified location. In comparison, we can show that the device or a collaborator has a presence at the specified location.

The idea of using time-of-flight to estimate distance is not a new one: it dates back to the birth of radar systems, which often use time-difference-of-arrival (TDOA) to determine the range to detected objects. Ultrasonic time-of-flight ranging can even be found in nature, where it is used by bats.

Coarse-grained location authentication has been used in the television industry to prevent cloning of set-top boxes [9]. Gabber and Wool propose four coarse-grained techniques, relying on extensive telecommunications infrastructure such as satellites, paging and cellular networks. Their techniques rely on tamper-resistant hardware.

Location-limited channels provide a communication mechanism that is restricted to a short range and provides both endpoints a mechanism to guarantee the authenticity of each participant [16]. Balfanz, et al., have proposed using location-limited channels for location-based access control [3], and many others have also proposed use of limited-range radio broadcasts as a way to verify proximity [13, 6, 5]. However, there are no strong security guarantees that the communication range will always be limited as desired: an adversary with more powerful equipment may be able to participate in the protocols even if they are substantially further away than non-malicious parties.

Finally, there are many techniques to help localize devices [2, 14, 15, 10, 18, 1], GPS being one of the most widely deployed. However, none of those works addressed security, and in fact, GPS signals can be spoofed [17, §3.2.2]. Nonetheless, we have noted that combining a (possibly insecure) localization mechanism with our secure location verification technique yields a secure localization algorithm.

(a) 10 randomly placed nodes; the nodes were constrained so that they were at least 20m away from all other nodes. This “constrained random” method corresponds to a reasonable, but not precise, dispersement of nodes. These 10 verifiers covered 81.5% of the room.

(b) 5 nodes manually placed to maximize coverage (93.3%)

Figure 8: Simulation results showing the effective ROA coverage area that a few verifier nodes can achieve in a 100m by 100m square room. The simulations show that the Echo protocol is quite effective, even with only a small number of verifier nodes.

Thus, insecure localization protocols should be seen as complementary to our work on secure location verification.

Many authors have commented on the value of location-based access control [7, 5, 3, 13, 6].

6. FUTURE WORK

One area for future work is performing more precise region verification using intersection (e.g., triangulation or trilateration). The idea is that if verifier v_1 can verify $\text{ROA}(v_1, \Delta)$ and v_2 can verify $\text{ROA}(v_2, \Delta)$, then together they should be able to verify $\text{ROA}(v_1, \Delta) \cap \text{ROA}(v_2, \Delta)$. The intuition is simple: if a prover is verified to be present in both regions, then it must be in their intersection. The allure of this approach is considerable: under our current scheme, a verifier node is required inside R , whereas in an intersection-based scheme, in principle nodes at the edges of, or even outside, R might suffice.

There are significant challenges to be surmounted before such an approach can be made compatible with security, though. First, the verifications would have to be done simultaneously; if not, the prover could move from location to another between the two runs. One way to do this is to have the prover receive both nonces and return a hash of their concatenation to both verifiers, who would have exchanged nonce information in advance. Another problem is that intersection-based protocols are not robust against collusion attacks by attackers with multiple nodes: such an adversary may legitimately have one node in $\text{ROA}(v_1, \Delta)$ and one node in $\text{ROA}(v_2, \Delta)$ independently without having any presence in $\text{ROA}(v_1, \Delta) \cap \text{ROA}(v_2, \Delta)$. It seems there re-

mains considerable work to be done before intersection can be applied in a full protocol.

7. CONCLUSION

We introduced the in-region verification problem. Then, we designed a provably secure, lightweight protocol to address it, named the Echo protocol. The Echo protocol does not require cryptography, time synchronization, or any prior agreement between the prover and verifier, making it suitable for low-cost devices such as those in sensor networks. It is robust against a malicious adversary with unbounded computing power; the security rests on physical properties of sound and RF signal propagation. We showed that for a reasonable scenario, coverage of 80–90% could be easily achieved, i.e., the Echo protocol could guarantee in-region verification for 80–90% of legitimate location claims. Consequently, we expect the Echo protocol to be a useful contribution in contexts where physical presence is used for access control.
